

## Write-Back Update Protocol

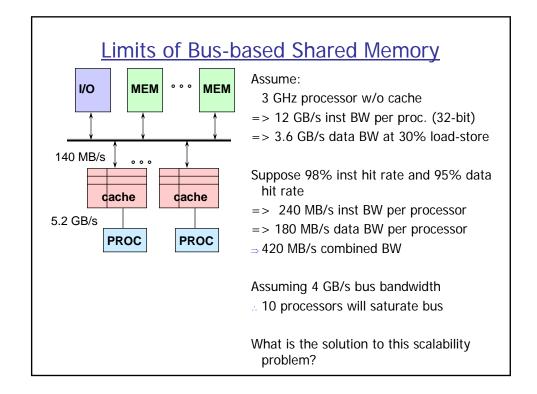

- Let's have a system where:
  - Write-backs happen when cache line is replaced
  - All writes result in updates of other caches caching the value
- Let's design the simplest write-back update protocol:
  - How many states should it have?
  - What are the significance of the states?

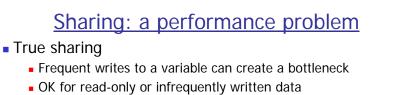

- Technique: make copies of the value, one per processor, if this is possible in the algorithm
- Example problem: the data structure that stores the freelist/heap for malloc/free
- False sharing
  - Cache block may also introduce artifacts
  - Two distinct variables in the same cache block
  - Technique: allocate data used by each processor contiguously, or at least avoid interleaving
  - Example problem: an array of ints, one written frequently by each processor
