**SOCIAL BIAS FRAMES:**
Reasoning about Social and Power Implications of Language

Abstract

**Warning:** this paper contains content that may be offensive or upsetting.

Language has the power to reinforce stereotypes and project social biases onto others. At the core of the challenge is that it is rarely what is stated explicitly, but rather the implied meanings, that frame people’s judgments about others. For example, given a statement that “we shouldn’t lower our standards to hire more women,” most listeners will infer the implicature intended by the speaker — that “women (candidates) are less qualified.” Most semantic formalisms, to date, do not capture such pragmatic implications in which people express social biases and power differentials in language.

We introduce **SOCIAL BIAS FRAMES**, a new conceptual formalism that aims to model the pragmatic frames in which people project social biases and stereotypes onto others. In addition, we introduce the Social Bias Inference Corpus to support large-scale modelling and evaluation with 150k structured annotations of social media posts, covering over 34k implications about a thousand demographic groups.

We then establish baseline approaches that learn to recover **SOCIAL BIAS FRAMES** from unstructured text. We find that while state-of-the-art neural models are effective at high-level categorization of whether a given statement projects unwanted social bias (80% $F_1$), they are not effective at spelling out more detailed explanations in terms of **SOCIAL BIAS FRAMES**. Our study motivates future work that combines structured pragmatic inference with commonsense reasoning on social implications.

1 Introduction

Language has enormous power to project social biases and reinforce stereotypes on people (Fiske, 1993). The way such biases are projected is rarely in what is stated explicitly, but in all the implied layers of meanings that frame and influence people’s judgments about others. For example, on hearing a statement that an all-Muslim movie was a “box office bomb”, most people can instantly

recognize the implied demonizing stereotype that “Muslims are terrorists” (Figure 1). Understanding these biases with accurate underlying explanations is necessary for AI systems to adequately interact in the social world (Pereira et al., 2016), and failure to do so can result in the deployment of harmful technologies (e.g., conversational AI systems turning sexist and racist; Vincent, 2016).

Most previous approaches to understanding the implied harm in statements have cast this task as a simple toxicity classification (e.g., Waseem and Hovy, 2016; Founta et al., 2018; Davidson et al., 2017). However, simple classifications run the risk of discriminating against minority groups, due to high variation and identity-based biases in annotations (e.g., which cause models to learn associations between dialect and toxicity; Sap et al., 2019a; Davidson et al., 2019). In addition, detailed explanations are much more informative for people to understand and reason about why a statement is potentially harmful against other people (Gregor and Benbasat, 1999; Ribeiro et al., 2016).

Thus, we propose SOCIAL BIAS FRAMES, a novel conceptual formalism that aims to model pragmatic frames in which people project social biases and stereotypes on others. Compared to semantic frames (Fillmore and Baker, 2001), the meanings projected by pragmatic frames are richer, and thus cannot be easily formalized using only categorical labels. Therefore, as illustrated in Figure 1, our formalism combines hierarchical categories of biased implications such as intent and offensiveness with implicatures described in free-form text such as groups referenced and implied statements. In addition, we introduce SBIC, a new corpus collected using a novel crowdsourcing framework. SBIC supports large-scale learning and evaluation with over 150k structured annotations of social media posts, spanning over 34k implications about a thousand demographic groups.

We then establish baseline approaches that learn to recover SOCIAL BIAS FRAMES from unstructured text. We find that while state-of-the-art neural models are effective at making high-level categorization of whether a given statement projects unwanted social bias (80% $F_1$), they are not effective at spelling out more detailed explanations by accurately decoding SOCIAL BIAS FRAMES. Our study motivates future research that combines structured pragmatic inference with commonsense reasoning on social implications.

Important implications of this study. We recognize that studying SOCIAL BIAS FRAMES necessarily requires us to confront online content that may be offensive or disturbing (see §7 for further discussion on the ethical implications of this study). However, deliberate avoidance does not eliminate such problems. Therefore, the important premise we take in this study is that assessing social media content through the lens of SOCIAL...
Bias Frames is important for automatic flagging or AI-augmented writing interfaces, where potentially harmful online content can be analyzed with detailed explanations for users or moderators to consider and verify. In addition, the collective analysis over large corpora can also be insightful for educating people on reducing unconscious biases in their language.

2 Social Bias Frames Definition

To better enable models to account for socially biased implications of language, we design a new pragmatic formalism that distinguishes several related but distinct inferences, shown in Figure 1. Given a natural language utterance, henceforth, post, we collect both categorical as well as free text inferences (described below), inspired by recent efforts in free-text annotations of commonsense knowledge (e.g., Speer and Havasi, 2012; Rashkin et al., 2018; Sap et al., 2019b) and argumentation (Habernal and Gurevych, 2016; Becker et al., 2017). The free-text explanations are crucial to our formalism, as they can both increase trust in predictions made by the machine (Kulesza et al., 2012; Bussone et al., 2015; Nguyen et al., 2018) and encourage a poster’s empathy towards a targeted group, thereby combating biases (Cohen-Almagor, 2014).

We base our initial frame design on social science literature of pragmatics (Lakoff, 1973; de Marneffe et al., 2012) and impoliteness (Kasper, 1990; Gabriel, 1998; Dynel, 2015; Vonasch and Baumeister, 2017). We then refine the frame structure (including number of possible answers to questions) based on the annotator (dis)agreement in multiple pilot studies. We describe each of the included variables below.

Offensiveness is our main categorical annotation, and denotes the overall rudeness, disrespect, or toxicity of a post. We consider whether a post could be considered “offensive to anyone”, as previous work has shown this to have higher recall (Sap et al., 2019a). This is a categorical variable with three possible answers (yes, probably, probably not, no).

Intent to offend captures whether the perceived motivation of the author was to offend, which is key to understanding how it is received (Kasper, 1990; Dynel, 2015), yet distinct from offensiveness (Gabriel, 1998; Daly, 2018). This is a categorical variable with four possible answers (yes, probably, probably not, no).

Lewd or sexual references are a key subcategory of what constitutes potentially offensive material in many cultures, especially in the United States (Strub, 2008). This is a categorical variable with three possible answers (yes, maybe, no).

Group implications are distinguished from individual-only attacks or insults that do not invoke power dynamics between groups (e.g., “F*ck you” vs. “F*ck you, f*ggot”). This is a categorical variable with two possible answers: individual-only (no), group targeted (yes).

Targeted group describes the social or demographic group that is referenced or targeted by the post. Here we collect free-text answers, but provide a seed list of demographic or social groups to encourage consistency.

Implied statement represents the power dynamic or stereotype that is referenced in the post. We collect free-text answers in the form of simple Hearst-like patterns (e.g., “women are ADJ”, “gay men VBP”; Hearst, 1992).

In-group language aims to capture whether the author of a post may be a member of the same social/demographic group that is targeted, as speaker identity changes how a statement is perceived (O’Dea et al., 2015). Specifically, in-group language (words or phrases that (re)establish belonging to a social group; Eble, 1996) can change the perceived offensiveness of a statement, such as reclaimed slurs (Croom, 2011; Galinsky et al., 2013) or self-deprecating language (Greengross and Miller, 2008). Note that we do not attempt to categorize the identity of the speaker. This variable takes three possible values (yes, maybe, no).

3 Collecting Nuanced Annotations

To create SBIC, we design a crowdsourcing framework to distill the biased implications of posts at a large scale.

3.1 Data Selection

We draw from various sources of potentially biased online content, shown in Table 2, to select
Could this post be considered offensive, disrespectful, or toxic to anyone/someone who is referred to/targeted by this post? —

English hate communities: Stormfront (de Gibert hashtags and slurs, respectively. 

lect datasets of tweets containing racist or sexist tweets. We also include tweets from Waseem and Hovy (2016) and Davidson et al. (2017), who collected microaggressions, on the other hand, are likely to have harmful implications, as posts are often made with intents to deride adversity or social inequality (Bicknell, 2007). Microaggressions, on the other hand, are likely to contain subtle biased implications—a natural fit for SOCIAL BIAS FRAMES.

In addition, we include posts from three existing English Twitter datasets annotated for toxic or abusive language, filtering out @-replies, retweets, and links. We mainly annotate tweets released by Founta et al. (2018), who use a bootstrapping approach to sample potentially offensive tweets. We also include tweets from Waseem and Hovy (2016) and Davidson et al. (2017), who collect datasets of tweets containing racist or sexist hashtags and slurs, respectively.

Finally, we include posts from known English hate communities: Stormfront (de Gibert et al., 2018) and Gab, which are both documented white-supremacist and neo-nazi communities (Bowman-Grieve, 2009; Hess, 2016), and two English subreddits that were banned for inciting violence against women (r/Incels and r/MensRights; Fingas, 2017; Center, 2012).

3.2 Annotation Task Design

We design a hierarchical annotation framework to collect biased implications of a given post (snippet shown in Figure 2) on Amazon Mechanical Turk (MTurk). The full task is shown in the appendix (Figure 4).

For each post, workers indicate whether the post is offensive, whether the intent was to offend, and whether it contains lewd or sexual content. Only if annotators indicate potential offensiveness do they answer the group implication question. If the post targets or references a group or demographic, workers select or write which one(s); per selected group, they then write two to four stereotypes. Finally, workers are asked whether they think the speaker is part of one of the minority groups referenced by the post.

We collect three annotations per post, and restrict our worker pool to the U.S. and Canada. We ask workers to optionally provide coarse-grained demographic information.4

Table 2: Breakdown of origins of posts in SBIC. Microaggressions are drawn from the Reddit corpus introduced by Breitfeller et al. (2019), and Banned Reds include r/Incels and r/MensRights.
Annotator demographics In our final annotations, our worker pool was relatively gender-balanced and age-balanced (55% women, 42% men, <1% non-binary; 36±10 years old), but racially skewed (82% White, 4% Asian, 4% Hispanic, 4% Black).

Annotator agreement Overall, the annotations in SBIC showed 82.4% pairwise agreement and Krippendorf’s $\alpha=0.45$ on average, which is substantially higher than previous work in toxic language detection (e.g., $\alpha=0.22$ in Ross et al., 2017). Broken down by each categorical question, workers agreed on a post being offensive at a rate of 76% (Krippendorf’s $\alpha=0.51$), its intent to offend at 75% ($\alpha=0.46$), and it having group implications at 74% ($\alpha=0.48$). For categorizing posts as lewd, workers agreed substantially (94%, $\alpha=0.62$). However, flagging potential in-group speech had lower agreement, likely because this is a very nuanced annotation, and because highly skewed categories (only 5% “yes”; see Table 3) lead to low $\alpha$ (here, $\alpha=0.17$ with agreement 94%).

Finally, workers agreed on the exact same targeted group 80.2% of the time ($\alpha=0.50$).

3.3 SBIC Description

After data collection, SBIC contains 150k structured inference tuples, covering 34k free text group-implication pairs (see Table 3). We show example inference tuples in Table 1.

Additionally, we show a breakdown of the types of targeted groups in Figure 3. While SBIC covers a variety of types of biases, gender-based, race-based, and culture-based biases are the most represented, which parallels the types of discrimination happening in the real world (RWJF, 2017).

We find that our dataset is predominantly written in White-aligned English (78% of posts), as measured by a lexical dialect detector by Blodgett et al. (2016), with <10% of posts having indicators of African-American English. We caution researchers to consider the potential for dialect- or identity-based biases in labelling (Davidson et al., 2019; Sap et al., 2019a) before deploying technology based on SBIC (see Section 7).

4 Social Bias Inference

Given a post, we establish baseline performance of models at inferring Social Bias Frames. An ideal model should be able to both generate the implied power dynamics in textual form, as well as classify the post’s offensiveness and other categorical variables. Satisfying these conditions, we use the OpenAI-GPT transformer networks (Vaswani et al., 2017; Radford et al., 2018, 2019) as a basis for our experiments, given their recent successes at
We cast our frame prediction task as a conditional generation task, where we linearize the variables following the frame hierarchy. At training time, our model takes as input a sequence of $N$ tokens:

$$x = \{\text{[STR]}, w_1, w_2, \ldots, w_n, \text{[SEP]}, w_{\text{[led]}}, w_{\text{[off]}}, w_{\text{[int]}}, w_{\text{[grp]}}, \text{[SEP]}, w_{\text{[g]1}}, w_{\text{[g]2}}, \ldots, \text{[SEP]}, w_{\text{[i]1}}, w_{\text{[i]2}}, \ldots, \text{[SEP]}, w_{\text{[i]}}, \text{[END]}\}$$  

where [STR] is our start token, $w_{1:n}$ is the sequence of tokens in a post, $w_{[g]}$, the tokens representing the group, and $w_{[i]}$, the implied statement. We add two task-specific vocabulary items for each of our five classification tasks ($w_{\text{[led]}}, w_{\text{[off]}}, w_{\text{[int]}}, w_{\text{[grp]}}, w_{\text{[i]}}$), each representing the negative and positive values of the class (e.g., for offensiveness, [offY] and [offN]).

The model relies on a stack of transformer blocks of multi-headed attention and fully connected layers to encode the input tokens (for a detailed modelling description, see Radford et al., 2018, 2019). Since GPT is a forward-only language model, the attention is only computed over preceding tokens. At the last layer, the model projects the embedding into a vocabulary-sized vector, which is turned into a probability distribution over the vocabulary using a softmax layer.

We minimize the cross-entropy of the contextual probability of the correct token in our full linearized frame objective (of length $N$):

$$L = -\frac{1}{N} \sum_i \log p_{\text{GPT}}(w_i | w_{0:i-1})$$

During training, no loss is incurred for lower-level variables with no values, i.e., variables that cannot take values due to earlier variable values (e.g., there is no targeted group for posts marked as non-offensive).

In our experiments we use pretrained versions of OpenAI’s GPT and GPT2 (Radford et al., 2018, 2019) for our model variants, named SBF-GPT$^1$ and SBF-GPT$^2$, respectively. While their architectures are similar (stack of Transformers), GPT was trained on a large corpus of fiction books, whereas GPT2 was trained on 40GBs of English web text.

**Inference** We frame our inference task as a conditional language generation task. Conditioned on the post, we generate tokens one-by-one either by greedily selecting the most probable one, or by sampling from the next word distribution, and appending the selected token to the output. We stop when the [END] token is generated, at which point our entire frame is predicted. For greedy decoding, we only generate our frames once, but for sampling, we repeat the generation procedure to yield ten candidate frame predictions and choose the highest scoring one under our model.

In contrast to training time, where all inputs are consistent with our frames’ structure, at test time, our model can sometimes predict combinations of variables that are inconsistent with the constraints of the frame (e.g., predicting a post to be non-offensive, but still predict it to be offensive to a group). To mitigate this issue, we also experiment with a constrained decoding algorithm (denoted “con-str”) that considers various global assignments of

---

We linearize following the order in which variables were annotated (see Figure 4). Future work could explore alternate orderings.

We binarize our categorical annotations, assigning 1 to “yes,” “probably,” and “maybe,”, and 0 to all other values.

4.1 Evaluation
We evaluate performance of our models in the following ways. For classification, we report precision, recall, and $F_1$ scores of the positive class. Following previous generative inference work (Sap et al., 2019b), we use automated metrics to evaluate model generations. We use BLEU-2 and RougeL ($F_1$) scores to capture word overlap between the generated inference and the references, which captures quality of generation (Galley et al., 2015; Hashimoto et al., 2019). We additionally compute word mover’s distance (WMD; Kusner et al., 2015), which uses distributed word representations to measure similarity between the generated and target text.

4.2 Training Details
As each post can contain multiple annotations, we define a training instance as containing one post-group-statement triple (along with the five categorical annotations). We then split our dataset into train/dev/test (75:12.5:12.5), ensuring that no post is present in multiple splits. For evaluation (dev., test), we combine the categorical variables by averaging their binarized values and re-binarizing using a .5 threshold, and compare the generated inferences (hypotheses) to all targeted groups and implied statements (references).

All experiments are carried out using HuggingFace’s Transformers library. We tune hyperparameters on the dev. set, and report performance for the best performing setting (according to average $F_1$). We train or finetune our models using a batch size of 4, a learning rate of $5 \times 10^{-6}$ for GPT and $10^{-5}$ for GPT2 (both with linear warm up), and consider training for $e \in \{1, 2, 5\}$ epochs.

5 Results
Listed in Tables 4 and 5, our modelling results indicate that making inferences about social biases in language is challenging for these models.

Classification Shown in Table 7, models perform well on higher-level variables such as offensiveness and lewdness, despite the latter being heavily skewed. We hypothesize that correctly predicting lewdness might require more lexical matching (e.g., detecting words with sexual connotations).

Whether a group is targeted is slightly less easy for models to predict, and whether the language is in-group is even more challenging, with most of the models defaulting to never predicting it. This highly skewed category poses a challenge for all models, likely due to subtlety of the task and the lack of positive instances. SBF-GPT₂-gdy is the only model that predicts positive values for in-group language, for which it benefits from constrained decoding with a 1.9% improvement in $F_1$ score (we show results with all constrained decoding variants in Table 7 in the appendix).

We only use the possible assignments in the same forward pass; we do not use assignments from different samples. In practice, as seen in Tables 4, 5, and 7, this only slightly improves predictions. We use GloVe trained on CommonCrawl, as part of the SpaCy en_core_web_md package.

### Generation

When evaluating our models on the generation tasks (i.e., targeted group and implied statement), we find that no one model outperforms others across all metrics (Table 5).

Overall, models do well at generating the targeted groups, likely because of the more limited generation space (there are only 1.4k possible groups in SBIC). Conversely, for implied statement generation (where output space is much larger), model performance is slightly worse.

Similar to the classification tasks, SBF-GPT$_2$-gdy shows a slight increase in RougeL score when using constrained decoding, but we see a slight drop in BLEU scores.

### Error analysis

Since small differences in automated evaluation metrics for text generation sometimes only weakly correlate with human judgments (Liu et al., 2016), we manually perform an error analysis on a manually selected set of generated development-set examples from the SBF-GPT$_2$-gdy-constr model (Table 6). Overall, the model seems to struggle with generating textual implications that are relevant to the post, instead generating very generic stereotypes about the demographic groups (e.g., in examples b and c). The model generates the correct stereotypes when there is high lexical overlap with the post (e.g., examples d and e). This is in line with previous research showing that large language models rely on correlational patterns in data (Sap et al., 2019c; Sakaguchi et al., 2020).

### Related Work

#### Bias and toxicity detection

Detection of hateful, abusive, or other toxic language has received increased attention recently (Schmidt and Wiegand, 2017), and most dataset creation work has cast this detection problem as binary classification (Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018). Moving beyond a single binary label, Wulczyn et al. (2017) and the PerspectiveAPI use a set of binary variables to annotate Wikipedia comments for several toxicity-related categories (e.g., identity attack, profanity). Similarly, Zampieri et al. (2019) hierarchically annotate a dataset of tweets with offensiveness and whether a group or individual is targeted. Most related to our work, Ousidhoum et al. (2019) create a multilingual dataset of 13k tweets annotated for five different emotion- and toxicity-related aspects, including a 16-class variable representing social groups targeted. In comparison, SOCIAL BIAS FRAMES not only captures binary toxicity and hierarchical information about whether a group is targeted, but also free-text implications about 1.4k different targeted groups and the implied harm behind statements.

Similar in spirit to this paper, recent work has tackled more subtle bias in language, such as microaggressions (Breitfeller et al., 2019) and condescension (Wang and Potts, 2019). These types of biases are in line with the biases covered by SOCIAL BIAS FRAMES, but more narrowly scoped.
Inference about social dynamics Various work has tackled the task of making inferences about power and social dynamics. Particularly, previous work has analyzed power dynamics about specific entities, either in conversation settings (Prabhakaran et al., 2014; Danescu-Niculescu-Mizil et al., 2012) or in narrative text (Sap et al., 2017; Field et al., 2019; Antoniak et al., 2019). Additionally, recent work in commonsense inference has focused on mental states of participants of a situation (e.g., Rashkin et al., 2018; Sap et al., 2019b). In contrast to reasoning about particular individuals, our work focuses on biased implications of social and demographic groups as a whole.

7 Ethical Considerations

Risks in deployment Automatic detection of offensiveness or reasoning about harmful implications of language should be done with care. When deploying such algorithms, ethical aspects should be considered including which performance metric should be optimized (Corbett-Davies et al., 2017), as well as the fairness of the model on speech by different demographic groups or in different varieties of English (Mitchell et al., 2019). Additionally, deployment of such technology should discuss potential nefarious side effects, such as censorship (Ullmann and Tomalin, 2019) and dialect-based racial bias (Sap et al., 2019a; Davidson et al., 2019). Finally, offensiveness could be paired with promotions of positive online interactions, such as emphasis of community standards (Does et al., 2011) or counter-speech (Chung et al., 2019; Qian et al., 2019).

Risks in annotation Recent work has highlighted various negative side effects caused by annotating potentially abusive or harmful content (e.g., acute stress; Roberts, 2016). We mitigated these by limiting the number of posts that one worker could annotate in one day, paying workers above minimum wage ($7–12), and providing crisis management resources to our annotators. In contrast to reasoning about particular individuals, our work focuses on biased implications of social and demographic groups as a whole.

8 Conclusion

To help machines reason about and account for societal biases, we introduce Social Bias Frames, a new structured commonsense formalism that distills knowledge about the biased implications of language. Our frames combine categorical knowledge about the offensiveness, intent, and targets of statements, as well as free-text inferences about which groups are targeted and biased implications or stereotypes. We collect a new dataset of 150k annotations on social media posts using a new crowdsourcing framework and establish baseline performance of models built on top of large pretrained language models. We show that while classifying the offensiveness of statements is easier, current models struggle to generate relevant social bias inferences, especially when implications have low lexical overlap with posts. This indicates that more sophisticated models are required for Social Bias Frames inferences.

Acknowledgments

We thank the anonymous reviewers for their insightful comments. Additionally, we are grateful to Hannah Rashkin, Lucy Lin, Jesse Dodge, Hao Peng, and other members of the UW NLP community for their helpful comments on the project. This research was supported in part by NSF (IIS-1524371, IIS-1714566), DARPA under the CwC program through the ARO (W911NF-15-1-0543), and DARPA under the MCS program through NIWC Pacific (N66001-19-2-4031).

Table 7: Full experimental results (%) of various models on the classification tasks (gdy: argmax, smp: sampling; constr: constrained decoding). Some models did not predict the positive class for “in-group language,” their performance is denoted by “–”. We bold the $F_1$ scores of the best performing model(s) on the development set. For easier interpretation, we also report the percentage of instances in the positive class in the development set.
Task

Post

${post}
- crawled from ${source}.

1.a) Could this post be considered offensive, disrespectful, or toxic to anyone/someone?
   ○ Yes, this could be offensive
   ○ Maybe, I’m not sure
   ○ No, this is harmless
   ○ I don’t understand the post

1.b) Was the intent of this post to be offensive/disrespectful to anyone?
   E.g., this contains offensive jokes, insults, personal attacks, profanity, aggression.
   ○ Yes, definitely
   ○ Yes, probably
   ○ No, probably not
   ○ No, definitely not

2) Does this post contain or allude to sexual content/acts?
   This includes euphemism, double entendre, etc.
   ○ Yes
   ○ Maybe
   ○ No

3) Who is referred to/targeted by this post? — Select all identity-based groups that apply.

3.a) Does the post imply offense/disrespect to an identity-related group of people?
   E.g., is this just a insult to one person (“Fuck you”, “All y’alls are morons”), or an offensive comment/insult about a whole identity-based group (“Fuck muslims”, “Fuck you, you stupid nigger”).
   ○ Yes, this could be offensive to a group (minority, identity-based, etc.)
   ○ No, this is just an insult to an individual or a non-identity-related group of people.

3.b) Which identity group is referred to in this post?
   ○ black folks
   ○ asian folks
   ○ latino/latina folks
   ○ native american/first nation folks
   ○ other

3.c) What aspect/stereotype/characteristic of this group (often unfairly assumed) is referenced or implied by this post? — Use simple phrases and do not copy paste from the post.
   i.e., actions/characteristics that US society (usually wrongly) associates with the group
   GROUP does ___
   GROUP does ___
   [optional]
   [optional]

3.d) Does the author of the post sound like they belong to the same minority group that is referred to by this post?
   Try your best to guess. For example, posts with “nigga” in them usually come from black authors. Additionally, members sometimes make fun of their own community.
   ○ Yes
   ○ Maybe
   ○ No

Figure 4: Snippet of the annotation task used to collect SBIC. The collection of structured annotations for our framework is broken down into questions pertaining to offensiveness, intent of the post, targeted group and minority speaker.
